

Is the Over-dispersed Poisson Model Underlying the Chain Ladder Algorithm?

Thomas Mack and Gary Venter

Abstract

It is shown that the (over-dispersed) Poisson model is not the same as the distribution-free chain ladder model of Mack (1993) although it yields the same estimator for the claims reserve. Moreover, the distribution-free chain ladder model has more in common with the historical chain ladder algorithm, and so it better qualifies to be referred to as the model underlying the chain ladder algorithm.

Overview of the two models

Let D_{ij} denote the cumulative losses for accident year $i=1, \dots, n$ and for age $j=1, \dots, n$. The loss amounts D_{ij} have been observed for $j \leq n+1-i$ whereas the other amounts, especially the ultimate amounts D_{in} , $i > 1$, have to be predicted. The chain ladder algorithm consists of the stepwise prediction rule

$$D_{ij}^{\wedge} = D_{i,j-1}^{\wedge} f_j^{\wedge} \quad \text{with} \quad f_j^{\wedge} = (\sum_i D_{ij}) / (\sum_i D_{i,j-1})$$

starting with the most recent cumulative claims amount $D_{i,n+1-i}^{\wedge} = D_{i,n+1-i}$ of accident year i . This yields

$$D_{in}^{\wedge} = D_{i,n+1-i}^{\wedge} f_{n+2-i}^{\wedge} \cdot \dots \cdot f_n^{\wedge}$$

as estimator for the ultimate claims amount.

The chain ladder algorithm was developed as a deterministic algorithm and did not have any stochastic model underlying it. But in order to assess its prediction error, an underlying stochastic model is required. In the last two decades, several models were associated with the chain ladder algorithm, but most of them lead to estimators for D_{in} which are different from the above D_{in}^{\wedge} , see e.g. Mack (1994) or England/Verrall (1998). In this paper, the only two models which lead to the same estimators for D_{in} as the chain ladder algorithm are compared.

Consider first the distribution-free stochastic model ("DFCL") of Mack (1993). Its main assumption is

$$(DFCL1) \quad E(D_{ij} \mid D_{i1}, D_{i2}, \dots, D_{i,j-1}) = D_{i,j-1} f_j$$

with unknown parameters f_2, \dots, f_n . From DFCL1 it can be deduced that

$$E(D_{in} \mid D_{i1}, \dots, D_{i,n+1-i}) = D_{i,n+1-i} f_{n+2-i} \cdot \dots \cdot f_n$$

which immediately gives the chain ladder algorithm if the unknown parameters f_j are estimated by f_j^{\wedge} . It is important to realize that in claims reserving the relevant quantity to be estimated is the conditional mean of D_{in} given the data observed so far because these data are a part of the quantity D_{in} of interest. In Mack (1993) it is shown that f_j^{\wedge} is the minimum variance unbiased linear estimator of f_j if one makes the following additional assumptions:

$$(DFCL2) \quad \text{Var}(D_{ij} \mid D_{i1}, \dots, D_{i,j-1}) = D_{i,j-1} \sigma_j^2 \quad \text{with unknown parameters } \sigma_j^2.$$

$$(DFCL3) \quad \text{The accident years } (D_{i1}, \dots, D_{in}), 1 \leq i \leq n, \text{ are independent.}$$

If DFCL2 is violated, some other variant of the chain ladder algorithm might still be optimal, as will be discussed further below. Failure of DFCL3 usually requires a different approach.

Already in 1975, Hachemeister and Stanard discovered another stochastic model leading to the chain ladder algorithm. This model works on the incremental amounts

$$C_{i1} = D_{i1} \quad \text{and} \quad C_{ij} = D_{ij} - D_{i,j-1}, \quad j > 1,$$

and makes the assumptions

(P1) $E(C_{ij}) = x_i y_j$ with unknown parameters x_i and y_j .

(P2) Each C_{ij} has a Poisson distribution.

(P3) All C_{ij} are independent.

Then the ML estimator R_i^{\wedge} of the claims reserve

$$R_i = C_{i,n+2-i} + \dots + C_{in} = D_{in} - D_{i,n+1-i}$$

turns out to give the same prediction $D_{in}^{\wedge} = D_{i,n+1-i} + R_i^{\wedge}$ as the chain ladder algorithm. Due to the independence assumption P3, $D_{i,n+1-i} + R_i^{\wedge}$ is an estimator of the conditional expectation $E(D_{in} | D_{i1}, \dots, D_{i,n+1-i})$. Assumption P2 implies that all incremental amounts C_{ij} have to be non-negative integers.

This Poisson model can be cast into the form of a Generalized Linear Model (GLM) with logarithmic link function via (cf. Renshaw/Verrall (1994))

(P1*) $\ln(E(C_{ij})) = \alpha_i + \beta_j$.

In this form, the parameters $\alpha_i = \ln(x_i)$, $\beta_j = \ln(y_j)$ can be estimated using standard statistical GLM software. Of course, this yields the same estimators for x_i , y_j , R_i and D_{in} because the estimation procedure of GLMs is maximum likelihood, too. A further benefit of the use of GLMs is the fact that these show a way how to overcome the constraint that C_{ij} have to be non-negative integers. For this purpose, we recall that the only distributional assumptions used in GLMs are the functional relationship between variance and mean and the fact that the distribution belongs to the exponential family. This relationship is $\text{Var}(C_{ij}) = E(C_{ij})$ in the Poisson case. It can be generalized to $\text{Var}(C_{ij}) = \phi E(C_{ij})$ without any change in form and solution of the likelihood equations. This allows for more dispersion in the data and one does not care any more about the range of the underlying distribution; one speaks of an over-dispersed Poisson model and of quasi-likelihood equations. For the solution of the quasi-likelihood equations it is not necessary that the C_{ij} 's are non-negative or integers. At least, the fitted values are always positive. However, the algorithm for the solution of the quasi-likelihood equations breaks down unless the sum of the observed incremental amounts in every row and every column is non-negative as can easily be seen from the quasi-likelihood equations

$$\sum_j \exp(\alpha_i + \beta_j) = \sum_j C_{ij}, \quad 1 \leq i \leq n,$$

$$\sum_i \exp(\alpha_i + \beta_j) = \sum_i C_{ij}, \quad 1 \leq j \leq n.$$

But these problems can be overcome if we work without the log-link and without GLM software. Then the over-dispersed Poisson model ("ODP") is:

(ODP1) $E(C_{ij}) = x_i y_j$ with unknown parameters x_i , y_j .

(ODP2) $\text{Var}(C_{ij}) = \phi E(C_{ij})$ with an unknown parameter ϕ .

(ODP3) All C_{ij} are independent.

The resulting quasi-likelihood equations are

$$\sum_j x_i y_j = \sum_j C_{ij}, \quad 1 \leq i \leq n,$$

$$\sum_i x_i y_j = \sum_i C_{ij}, \quad 1 \leq j \leq n.$$

As has been shown in appendix A of Mack (1991) (see also Schmidt/Wünsche (1998)), these equations have the unique solution (if all f^{\wedge}_j are well-defined and $\neq 0$)

$$x^{\wedge}_i y^{\wedge}_j = D_{i,n+1-i} f^{\wedge}_{n+2-i} \dots \cdot f^{\wedge}_{j-1} \cdot (f^{\wedge}_j - 1) \quad \text{for } j > n+1-i,$$

$$x^{\wedge}_i y^{\wedge}_j = D_{i,n+1-i} ((f^{\wedge}_{j+1} \dots \cdot f^{\wedge}_{n+1-i})^{-1} - (f^{\wedge}_j \dots \cdot f^{\wedge}_{n+1-i})^{-1}) \quad \text{for } j \leq n+1-i,$$

with f^{\wedge}_j from the chain ladder algorithm. Because $(f^{\wedge}_j - 1) + f^{\wedge}_j \cdot (f^{\wedge}_{j+1} - 1) = f^{\wedge}_j \cdot f^{\wedge}_{j+1} - 1$ we immediately obtain

$$R^{\wedge}_i = x^{\wedge}_i y^{\wedge}_{n+2-i} + \dots + x^{\wedge}_i y^{\wedge}_n = D_{i,n+1-i} (f^{\wedge}_{n+2-i} \dots \cdot f^{\wedge}_n - 1).$$

This shows that the solution of the quasi-likelihood equations of the ODP model gives the same estimator for D_{in} as the chain ladder algorithm and as the DFCL model. We will find some restrictions later.

Evidence that the models are different

In view of the fact that both models, DFCL1-3 and ODP1-3, yield the same estimators R^{\wedge}_i and D^{\wedge}_{in} as the deterministic chain ladder algorithm, the questions arise whether one model is a special case of the other and whether both models can be called “underlying the chain ladder algorithm”. First, we give five arguments, each of which shows that the models are different.

a) ODP has more parameters than DFCL:

In ODP1, one of the parameters is redundant because replacing x_i with x_i/c and y_j with $y_j \cdot c$ yields the same model. Therefore ODP has $2n-1$ parameters whereas DFCL has only $n-1$ parameters f_2, \dots, f_n . If we make the parametrisation of ODP1 unique by requiring that $y_1 = 1$, then we have a one-to-one relationship between the set of the y^{\wedge}_j s and the set of the f^{\wedge}_j s:

$$f^{\wedge}_j = (y^{\wedge}_1 + \dots + y^{\wedge}_j) / (y^{\wedge}_1 + \dots + y^{\wedge}_{j-1})$$

$$y^{\wedge}_j = f^{\wedge}_2 \dots \cdot f^{\wedge}_{j-1} \cdot (f^{\wedge}_j - 1), \quad j > 1.$$

In this case ($y_1 = 1$) we have $x_i = E(C_{i1}) = E(D_{i1})$ which shows that ODP uses parameters which are not used by the chain ladder algorithm. In the DFCL model, $D_{i,n+1-i}$ cannot be considered a parameter because it is known with certainty and does not lead to any estimation error. Moreover, $D_{i,n+1-i}$ does not play a specific role in the model assumptions: If one would consider it a parameter, this was to be done for all D_{ij} known, too. The additional parameters x_i of ODP make it possible that within ODP the unconditioned means $E(D_{ij})$ can be estimated, too. This is not possible within the DFCL model.

b) ODP has stronger independence assumptions:

ODP3 requires all cells C_{ij} to be independent whereas DFCL3 only requires that all rows are independent. The latter can often be assumed to hold in practise, whereas the independence of C_{ij} and $C_{i,j+1}$ is sometimes violated. Even the uncorrelatedness of C_{ij} and $C_{i,j+1}$ cannot be deduced from DFCL1-3.

c) The fitted values C^{\wedge}_{ij} or D^{\wedge}_{ij} and therefore also the residuals $r_{ij} = C^{\wedge}_{ij} - C_{ij}$ for ODP are different from those of DFCL:

The fitted value D^{\wedge}_{ij} for $j \leq n+1-i$ for the DFCL model clearly is

$$D^{\wedge}_{ij} = D_{i,j-1} f^{\wedge}_j \quad \text{or} \quad C^{\wedge}_{ij} = D_{i,j-1} (f^{\wedge}_j - 1).$$

Note that there are no fitted values for the first column $D_{i1} = C_{i1}$.

The fitted value D^{\wedge}_{ij} for $j \leq n+1-i$ for the ODP model is

$$C_{ij}^{\wedge} = x_i^{\wedge} y_j^{\wedge} = D_{i,n+1-i} \left((f_{j+1}^{\wedge} \dots f_{n+1-i}^{\wedge})^{-1} - (f_j^{\wedge} \dots f_{n+1-i}^{\wedge})^{-1} \right),$$

which yields

$$D_{ij}^{\wedge} = D_{i,n+1-i} / (f_{j+1}^{\wedge} \dots f_{n+1-i}^{\wedge})$$

which is different from DFCL, because e.g. for $j=n+1-i$ we obtain $D_{i,n-i} \cdot f_{n+1-i}^{\wedge}$ as fitted value for DFCL and $D_{i,n+1-i}$ as fitted value for ODP which are different for $i > 1$ because f_{n+1-i}^{\wedge} depends not only on $D_{i,n+1-i}/D_{i,n-i}$ of accident year i but also on the corresponding ratios of all older accident years, too.

d) The simulated future emergence is different:

To simulate the future values of C_{ij} for ODP, all their expected values could be calculated, and then random draws added. For DFCL, on the other hand, the first new diagonal could be simulated this way, but for the second new diagonal the simulated cumulative value for the first diagonal would have to be multiplied by the development factor to get the mean value for the second diagonal. This mean thus includes the random component simulated for the first diagonal, which is not the case for the ODP simulation.

e) The true expected reserves $E(R_i | \text{data})$ are different:

If we would know the true parameters f_2, \dots, f_n and x_i, y_j , respectively and if it was possible to draw several sets of observations (run-off triangles $\{D_{ij}, i+j \leq n+1\}$) from the same "population", then the reserve estimator $R_i^{\wedge} = D_{i,n+1-i} (f_{n+2-i} \dots f_n - 1)$ of the chain ladder algorithm as well as of the DFCL model would change from one random draw to the next as $D_{i,n+1-i}$ changes, but the reserve estimator $x_i y_{n+2-i} + \dots + x_i y_n$ of the ODP model would not.

Conclusion:

Whereas after a) and b) ODP could still seem to be a refinement of DFCL, c), d) and e) show that the models are definitively different. As a consequence, especially from d), the prediction errors of the models are different, too. For the formulae of the prediction errors see Mack (1993) for the DFCL model and England/Verrall (1998) for the ODP model.

In each of these areas of difference, the DFCL agrees with the chain ladder algorithm to the extent that the algorithm has a clear implication. For instance, the chain ladder algorithm does not compute any parameters other than the development factors, and if you wanted to measure goodness-of-fit for the chain ladder algorithm, you would calculate the fitted values as the development factors times the previous cumulative losses. The ODP differs from the chain ladder in these aspects.

As a consequence, the prediction errors calculated with the bootstrap approach of England and Verrall (1998) differ from the prediction errors for the chain ladder algorithm. A bootstrap approach to the chain ladder prediction errors would consist of resampling the individual development factors $F_{ij} = D_{ij}/D_{i,j-1}$ within each column j .

Other differences between the ODP model and the CL algorithm

The chain ladder algorithm leads to closely related alternatives when the data is not exactly as required, and these alternatives can be readily accommodated by the DFCL model with appropriate adjustments to the assumptions. This is not the case with the ODP in the following two examples.

1) ODP does not work in all situations where the CL algorithm works:

In practise, it often happens that the figures of the oldest calendar years are not available. This means that the run-off triangle $\{D_{ij} | i+j \leq n+1\}$ changes its shape to a trapezoid $\{D_{ij} | m \leq i+j \leq n+1\}$ with $m \leq n$. Then the ODP model does not yield estimators R_i^{\wedge} identical to the DFCL

model and chain ladder algorithm. This is most easily seen for the following trapezoid (missing D_{11}):

D_{12}	D_{13}	with incremental amounts	C_{13}
D_{21}	D_{22}		C_{21} C_{22}
D_{31}			C_{31}

where C_{12} cannot be known because otherwise one would also know $D_{11} = D_{12} - C_{12}$. In this situation the ODP model clearly cannot be applied (4 observations for 5 parameters) but both, chain ladder algorithm and DFCL model, can (with $f^{\wedge}_2 = D_{22}/D_{21}$, $f^{\wedge}_3 = D_{13}/D_{12}$) and yield identical results. Here, the disadvantage of the additional parameters x_i of the ODP is clearly exhibited.

More generally, if one or several claims amounts somewhere in the run-off triangle are not known or omitted as being not credible (e.g. a typing error or a large individual claim whose amount is not known), then the ODP yields different estimations for D_{in} from chain ladder algorithm (and from DFCL). The reason is the fact that the proof for the identity

$$x^{\wedge}_i \cdot y^{\wedge}_j = D_{i,n+1-i} \cdot f^{\wedge}_{n+2-i} \cdot \dots \cdot f^{\wedge}_{j-1} \cdot (f^{\wedge}_j - 1) \quad \text{for } j > n+1-i,$$

only works for a full triangle without any missing values.

2) ODP can not be adapted if the weights in f^{\wedge}_j are changed:

In practise, the estimator for f_j is often calculated in a different way from f^{\wedge}_j , e.g.

$$f^{\wedge}_j = (\sum_i D_{ij}/D_{i,j-1}) / (n+1-j) \quad \text{(straight average)}$$

or

$$f^{\wedge}_j = (\sum_i D_{i,j-1} \cdot D_{ij}) / (\sum_i D_{i,j-1}^2) \quad \text{(regression method as in Kremer 1984).}$$

These estimators lead to different estimators for R_i and D_{in} from those based on f^{\wedge}_j . It is obvious, that the DFCL model can easily be adapted to these estimators via

$$\text{(DFCL2')} \quad \text{Var}(D_{ij} \mid D_{i1}, \dots, D_{i,j-1}) = D_{i,j-1}^2 \sigma_j^2$$

or

$$\text{(DFCL2'')} \quad \text{Var}(D_{ij} \mid D_{i1}, \dots, D_{i,j-1}) = \sigma_j^2.$$

But if one tries to adapt ODP3 to

$$\text{(ODP3')} \quad \text{Var}(C_{ij}) = \phi(E(C_{ij}))^2 \quad \text{(Gamma-GLM, cf. Mack (1991))}$$

or

$$\text{(ODP3'')} \quad \text{Var}(C_{ij}) = \phi \quad \text{(least squares method of DeVyllder 1978),}$$

one obtains estimators for R_i and D_{in} which are again different from those of the CL algorithm with f^{\wedge}_j or f^{\wedge}_j , respectively. There are no other variance assumptions known under which ODP could be adapted to give the same predictions as the chain ladder algorithm with f^{\wedge}_j or f^{\wedge}_j .

Conclusion

The DFCL and ODP models are different and they yield the same predictions only in a special but common situation. But even then, their prediction errors are different. Because the DFCL model agrees with the chain ladder algorithm in every identified area, whereas the ODP does not, just the DFCL model can reasonably be called "underlying the chain ladder algorithm."
